Neurotransmitters - act locally & rapidly

→ When an electric signal via (potential) arrive @ the synaptic terminal they diffuse across the synaptic cleft * i.e the gap between the receiving - & sending neuron. or muscle cell

Once the neurotransmitters is transduced into a response such as continued electrical signaling or modification of cellular response → the target cell responds within milliseconds of receiving the chemical "message" this response then ceases very quickly once the signaling ends.

For neural comm. → enables body function that involve quick, brief actions, movement sensation & cognition.

Endocrine Sys → Uses only 1 method; → this is chemical → secretion of hormones. → into the extracellular fluid.

Hormones are transported primarily via blood stream bind to receptors on target cells → including a characteristic response. As a result, endocrine signaling requires more time than neural signaling to prompt a response from target cells.
