→ This allows Ca^{2+} to enter the cell further depolarizing it at a more rapid rate until it reaches a value of approx. +15 mV ⇒ when this is reached the Ca^{2+} channel close & K^+ channels → open → allowing outflux of K^+ → which results in repolarization.

→ The membrane potential reaches −6φ mV, the K^+ channels close Na^+ channels open

~~Membrane~~ Action Potential of the SA Node. The prepotential is due to slow inflax of Na^+ until the threshold is reached followed by a rapid depolarization & repolarization. The prepotential accounts for the membrane reaching threshold & initiates the spontaneous depolarization & contraction of the
