AP (19.2)(36) "ϕ. 16.

Membranes → Potentials & Ion Movement 2ϕ26
in [Cardiac Contractile Cells]

Here is a distinctly different electrical pattern involving the contractile cells. There is rapid depolarization followed by a plateau phase & then repolarization.

The ~~pheo~~ phenomen accounts for the long refactory periods required for the cardiac muscle cells to pump blood effectively before they are capable of firing 2nd time. These Cardiac myocytes normally do not init their own potential but ~~out~~ wait for an impulse to reach them.

stable resting → conductive cells @
approx -8ϕ mV → for atria
while -90 mV → for ventricles

Despite the initial difference, the ~~outer~~ components of their action potentials are virtually identical. In both cases, when ~~si~~ stimulated by an actior potential, voltage-gated channels rapidly open → beginning the positive-feedback mechanism of depolarization.

Rapid infux raises the membrane potential by $+3\phi$ mV → thus closing the Na^+ channel

~~Ptatue~~ Plateau Phase → after the depolarization here is a plateau phase.
which membrane
Due to a large part to the opening of the Ca^{2+} channels / close & k^+ channels ~~open~~ open, allowing K^+ to
